

Treatment of Cluster Headache in a Different Light: A Case Study

Arnold Wilkins and Nicholas Cooper

Department of Psychology, University of Essex, Colchester, UK

We report on a patient with cluster headache who wore spectacles tinted to provide maximum comfort when reading printed text. The spectacles absorbed short-wavelength light and were only worn during the prodrome period. The patient has been free of cluster headaches for the 6 years since the spectacles became available, and the prodromes have decreased in severity and frequency. The hypothalamus is highly active during cluster headaches and receives visual input from the intrinsically photosensitive retinal ganglion cells (ipRGCs). The ipRGCs are most sensitive to short-wavelength light.

A university lecturer first experienced headaches during the summer of 1989, when he was aged 26 years. The headache periods initially lasted about 1 day and because the pain was in the trigeminal area both an optometrist and a dentist were consulted. The headaches gradually increased in length, severity and frequency over the ensuing 10 years, typically lasting 4–6 weeks every other year, and always in late spring or early summer. Each headache typically lasted 45–90 minutes and occurred 3–5 times per day. The episodes, now recognized as cluster headache, were preceded by 2–4 weeks of prodromes, known to the patient as ‘shadows’. The prodromes manifested as: 1) a unilateral feeling of pressure over the right trigeminal area (same side as the cluster headache pain) that could progress through ache to pain of moderate to severe intensity; 2) occasional feeling of blocked nasal passage (right side); 3) occasional mild neck pain. The symptoms could last from a few hours to an entire day, and built up in frequency and intensity over the course of about a month before the onset of the cluster headache period. Atypically, the prodrome also occurred in December of each year, but did not then develop into episodes of cluster headache. Occasionally, the patient could stop a prodrome from developing into a cluster using oral sumatriptan, but only rarely. The cluster headaches continued unaltered for 13 years until the patient was seen in 2002 at the National Hospital for Neurology and Neurosurgery, London UK. A CT scan and neurological examination were unremarkable. Pain management with subcutaneous sumatriptan was initiated and, in 2006, this was supplemented with oxygen. The patient has no other health issues. Both the patient’s parents had migraine.

In 2014, the patient was given a pair of light-weight spectacles with precision tints as part of a research project at his university.¹ The chromaticity of the lenses was selected using the Intuitive Colorimeter™ (Cerium Visual Technologies Ltd., Tenterden, UK).^{1,2} He chose a chromaticity (yellow-green) that best improved the clarity of and comfort when reading a page of text, and spectacle lenses were then made that provided this chromaticity under white (F2) fluorescent light. The spectral transmission of the lenses is shown in *Figure 1*. The lenses transmitted 56% of the light and their Uniform Chromaticity Scale chromaticity was $u' = 0.189$, $v' = 0.529$.

The patient discovered that his prodrome did not progress to a cluster headache when he was using the tinted spectacle lenses. When he put the spectacles on, the sensations of pressure and mild pain gradually dissipated rather than rising to the excruciating piercing pain of cluster headache. Between 2014 and 2021, he was able to avert innumerable prodromes by wearing the tinted lenses; he does not wear them at other times. Since the tinted spectacles were provided, he has not experienced a cluster headache and has not used sumatriptan and oxygen. Over these 6 years, the symptoms have become less pronounced and quicker to stop. By 2021, the prodromes had decreased to about 2 per year.

Informed consent and consent for publication were provided by the patient. Informed consent was received from the patient involved in this case study, and no identifying information or images have been included. The research project was approved by the University of Essex Ethics Committee, reference AW1203.

Discussion

Cluster headache is a disease of long duration, and when episodic it tends to worsen, particularly in male patients with a disease duration of over 20 years.³ In this case, however, the abrupt cessation of cluster attacks when the spectacles were first made available and the failure of repeated prodromes to progress to cluster headaches when the tinted spectacles were worn both suggest that the tint was preventing the progression of the cluster headache. The precision tint alleviated discomfort in and around the eye – the same location as the pain at the start of the cluster headache. The decrease in the frequency of prodromes suggests that the beneficial effect of the tint was not simply the prevention of the prodrome developing into an attack. Other longer term benefits also accrued possibly as a result of the abolition of headaches; spontaneous

improvement may also have been a factor.

In general, the light people choose as being comfortable for reading has a chromaticity close to the Planckian locus (i.e. similar to the various colours of daylight).^{4,5} In migraine with aura, however, the comfortable chromaticity lies distant from the Planckian locus and the colour is strongly saturated,^{4,5} as in this case. The tinted spectacles were yellow-green. Green light is better tolerated than light of other colours when the light is sufficiently bright to cause symptoms.⁶ The spectral transmission of the tint (*Figure 1*) absorbed short-wavelength light, where the intrinsically photosensitive retinal ganglion cells (ipRGCs) are most sensitive, with possible consequence for the pupillary response⁷ and light sensitivity.⁶ Neuroimaging studies have found that the hypothalamus is hyperactive during cluster headache attacks.^{9,10} The hypothalamus is known to have a visual input from the ipRGCs^{11,12} and may be involved in the circadian and seasonal nature of cluster headaches^{13,14} evident in this case.

The effects of the tinted spectacles may have occurred because their spectral transmission was individually selected for maximum comfort and/or because they attenuated short-wavelength light. Vingen et al.¹⁵ found a self-reported frequency of photophobia in 91% of 50 patients with cluster headache, and about 20% of patients report bright or flashing light as triggers.¹⁶ The Intuitive Colorimeter allows an ophthalmic tint to be designed individually to reduce photophobia.^{1,2,17,18}

Photophobia may be an important component of the prodrome in cluster headache, and when treated, the reduction in photophobia can sometimes evidently prevent the progression to cluster headache. As a single case report, this study has obvious limitations, and it remains to be seen whether other patients with cluster headache can benefit from precision tints. **q**
